Abstract. The present paper investigates the Faraday effect and absorption and luminescence spectra of single-crystal TbF₃ measured at 90 K and 300 K. The optical-quality single-phase TbF₃ crystals (structural type β -YF₃) were grown by the Bridgman technique. Faraday rotation angles were measured at remagnetization along the [100] crystallographic axis. Low temperature optical measurements were carried out along the [100] axis. “Quasi-doublet” sublevels with energy at 0 cm⁻¹, 65 cm⁻¹ and 190 cm⁻¹, and also a singlet sublevel with energy at 114 cm⁻¹ located in the ground ⁷F₆ multiplet were determined from the low temperature luminescence spectra. The Van-Vleck behavior of the magnetic susceptibility χ_b can be satisfactorily explained by the magnetic mixing of wave functions belonging to the ground and first excited “quasi-doublet” sublevels at 0 and 65 cm⁻¹, respectively. Analysis of the oscillation dependences of the rotation angle showed that the value of the natural birefringence ($\Delta n \approx 0.0186$) remains nearly constant within the wavelength and temperature ranges under investigation. As the temperature decreases, we find significant increases in the oscillation amplitude of the rotation angle and in the Verdet constant V . The spectral dependences $V(\chi)$ are linear throughout the temperature range. The magneto-optical activity of TbF₃ can be explained by means of the spin- and parity-allowed electric-dipole $4f \rightarrow 5d$ transitions in the Tb³⁺ ions.

I. Introduction

Trifluorides of rare-earth ions [1] at low temperature demonstrate a wide variety of magnetic properties, which makes their investigation interesting for theoretical studies of magnetic ordering. For instance, in the 1970s, ferromagnetic ordering of the Tb³⁺ magnetic moment was unexpectedly revealed in a study of the temperature dependence of the magnetic susceptibility and specific heat capacity in orthorhombic crystals ($T_C = 3.95$ K) [2], in contrast to other RE crystals with rhombic symmetry, where antiferromagnetic ordering is usually observed at a low temperature ($T_N \leq 3.8$ K) [3].

Crystallographic properties of trifluorides such as CeF₃, PrF₃, NdF₃ differ greatly from those of HoF₃ and TbF₃. The CeF₃ and NdF₃ crystals have a the hexagonal tisonite-type structure (space group $P-3c1$) [1,4,5] with the third-order optical axis coinciding with the crystallographic c -axis. This has allowed for detailed investigation of the Faraday effect (FE) in an external magnetic field (0 – 15 kOe) oriented along the c -axis of these crystals within a wide temperature range (4.2 – 300

K). Interest in potential applications of these trifluorides in magneto-optical devices [6] is mainly due to their high transparency in a wide spectral range (0.2 – 6 μm) [7] and superior mechanical properties in comparison with other crystalline materials such as the rare-earth chlorides [8].

By contrast, the crystal structure of TbF_3 (and HoF_3) has orthorhombic symmetry (space group $Pnma$) [9] and is called a “quasi-uniaxial crystal,” as the optical axis does not coincide with a crystallographic axis of the orthorhombic structure (a , b , c). In this case, investigation of anisotropic materials in magneto-optical experiments must identify the precise orientation of the optical axis, since the presence of natural birefringence greatly complicates the measurement of the Faraday effect in any other orientation [10, 11]. For this reason, very few studies have been done to investigate the FE in trifluoride Tb^{3+} or Ho^{3+} crystals.

The present paper investigates the Faraday effect and absorption and luminescence spectra of single-crystal TbF_3 . The FE angles were determined from the temperature and spectral dependences of the rotation angles of the major axis of the polarization ellipse of light, measured at remagnetization of the crystal along the [100] axis in the wavelength 430–700 nm at 92 K and 300 K. The luminescence and absorption spectra were measured using unpolarized light in the spectral regions containing the visible and ultraviolet (UV) absorption bands, with a spectral resolution of 2 – 3 cm^{-1} for the optical absorption and 3 – 5 cm^{-1} for the luminescence spectra.

II. Measurement procedures and samples

The TbF_3 crystals were grown by the Bridgman technique using a graphite heater and multicellular crucibles. TbF_3 crystals were synthesized from terbium oxide Tb_4O_7 (99.998% purity) by the hydrofluoride method in a CF_4 (99.999% purity grade) atmosphere. The growth chamber was evacuated prior to growth by turbomolecular pumping to a pressure of 10^{-3} Pa. The growth was conducted with a temperature gradient in the growth zone of 80 K/cm and a crucible pulling rate of 3 mm/h. The postgrowth cooling rate was about 50 K/h.

The crystals obtained were up to 40 mm in diameter, with a slight rose tint, free of visually observed scattering inclusions (see **Fig. 1**). Occasionally, individual cracks along the (010) cleavage plane were observed in as-grown crystals. Oxygen contamination in the TbF_3 crystal was lower than 200 ppm, as assessed by the vacuum fusion technique. The single-crystal orientation was determined by the back-reflection Laue method. Crystals of optical quality were cut and polished along the main crystallographic (001), (010) and (001) planes. In the measurements of crystal properties, crystallographic axes of the samples were positioned to within 1 deg.

Phase characterization of crystals were performed on a *Rigaku MiniFlex 600 powder X-Ray diffractometer* using $\text{CuK}\alpha$ radiation in the 2θ range from 10° to 100° . Unit-cell parameters were calculated using the DICVOL program. The single-phase TbF_3 crystals belong to the structural type

β -YF₃ (space group *Pnma*) and have lattice parameters: $a = 6.5109$ Å, $b = 6.9482$ Å, and $c = 4.3886$ Å, in agreement with those reported in [9]. The refractive indices n_x , n_y , and n_z were measured by the refractometric method along the major crystallographic axes [100], [010] and [001]. The values for $\lambda = 0.589$ μm are $n_x = n_g = 1.602$, $n_y = n_m = 1.588$ and $n_z = n_p = 1.569$, close to data published in [12].

The absorption and fluorescence spectra were obtained with a high resolution diffraction monochromator MDR Model 23 (LOMO, Russia). The average instrumental resolution was 0.03 nm for the absorption spectra and 0.05 nm for the fluorescence measurements in the wavelength range covered. Both the excitation and luminescence observations were done in a longitudinal geometry. Nonpolarized photoexcitation was produced by a mercury lamp with a UV filter. Detection of the absorption spectra was made using photomultiplier tubes sensitized by a technique described previously that stabilizes the average photomultiplier current at a constant level while scanning over a given line shape [13]. Optical spectra were recorded at 92 K and 300 K. For low temperature measurements the crystal was attached to a cold finger of conduction Dewar filled with liquid nitrogen ($T = 78$ K).

Measuring the Faraday effect for TbF₃ in the orthorhombic crystal is challenging, due to the large background natural birefringence $\Delta n \sim 10^{-2}$ [10, 11, 14, 17]. The measured double-angle θ tangent to the major-axis polarization ellipse rotation has an oscillatory character that depends on the wavelength λ , crystal thickness l , and temperature T [14,17]. The amplitude of the oscillations of the double-angle θ is proportional to the Faraday effect angle α_F , and the period of the oscillations is proportional to the magnitude of the natural birefringence Δn [14,17]. Note that the angle θ is small, with values of a few arc minutes in a field of 10 kOe in the visible spectral range [15, 16].

Additionally, the value of the natural birefringence ($\sim 10^{-2}$) complicates interpretation of precise optical measurements due to observation of the strongly oscillating dependence of the rotation angle of the major axis θ on the wavelength and temperature. Due to this feature, we use a highly sensitive method of dynamic registration to measure the angle θ [14,17]. In this case, the angle is defined by a relative change of the intensity of light passed through the “polarizer-sample-analyzer” optical system in an external magnetic field. Magnetic reversal of the sample results in periodicity of the rotation angle θ with the frequency of the alternating magnetic field H . Hence, light flux coming into the photodetector consists of two terms: an alternating signal related to the rotation of the plane of light polarization (or major axis of the polarization ellipse) $\Delta I = (I - I_0)$, and a constant signal I_0 , with intensity defined by the light flux passing through the “polarizer-sample-analyzer” optical system at $H = 0$. Using the Jones matrix [10], which describes relative

amplitudes and phases of the components of the electrical vector of the light flux passing through the magnetized orthorhombic sample [10], we consider the case of the transmission plane of the polarizer (P) oriented parallel to one of the crystal axis of the orthorhombic crystal, with a 45 deg angle between transmission planes of the polarizer (P) and analyzer (A). Then, the total light intensity I on the photodetector can be described as:

$$I = I_0(1 \pm \sin \chi \cdot \sin \Phi) \quad (1)$$

where χ is the magnetooptical parameter defined by the off-diagonal element ε' of the dielectric tensor $\hat{\varepsilon}$, whose modulus is proportional to an external magnetic field H ; and $\Phi = \frac{2\pi}{\lambda} \Delta n \cdot l$ is the phase shift arising between the two orthogonal elliptically-polarized normal modes propagating into the rhombic crystal in the z -axis direction [10, 11], with l being the thickness of the crystal. The $\pm$ signs correspond to the two orthogonal positions of the transmission plane of the polarizer relative to the crystal axes. Hence, the expression describing the relative change of the light intensity $\delta = \frac{(I - I_0)}{I_0}$ passing through the magnetized orthorhombic crystal (in the approximation of large natural birefringence, $\Delta n \gg \varepsilon' / n$ [15,16]) can be represented as:

$$\delta = \frac{\Delta I}{I_0} = 2\theta = \frac{\varepsilon'}{n \cdot \Delta n} \cdot \sin\left(\frac{2\pi}{\lambda} \Delta n \cdot l\right) \quad (2)$$

since in the approximation of small rotation angles the relative change of the intensity δ defines the double rotation angle θ of the plane of polarization at the analyzer azimuth of 45 deg. Thus, in this experimental geometry, the relative change of the light intensity δ is an oscillating function of wavelength and temperature, with amplitude determined by the FE angle (since $\alpha_F \sim \varepsilon' / n$ [15,16]) and period determined by the value of natural crystallographic birefringence Δn . As a result, the FE of TbF_3 can be calculated from the spectral and temperature dependences of the rotation angle θ , which is measured along the [100] axis between 430-700 nm, and at 92 K and 300 K, with the experimental setup described below.

Light flux from a halogen lamp (KGM-100) passing the monochromator is focused by a lens on the sample placed in the electromagnet. The magnetic field alternates with a frequency of 80 Hz and amplitude of 7 kOe. A polarizer is placed before the sample, and the light passing the polarizer, sample and analyzer is focused on the photomultiplier cathode by another lens. The photomultiplier signal feeds a lock-in amplifier and synchronous detector, which are connected to a computer. The electromagnet is made of shell-type transformer core, which significantly reduces inductive interference on the measuring electronics from the modulating magnetic field. To make low temperature measurements, the samples are placed in a compact liquid nitrogen optical cryostat

made of thin-walled stainless steel. The rotation angle sensitivity of the setup is ≤ 0.1 arc minute in the visible range and is mainly controlled by the noise threshold of the measuring electronics. The relative error of the rotation angle measurement is 3 – 5%, and the positioning of the crystal axes is within 2 – 3 deg.

III. Experimental results and discussion

3.1. Absorption and luminescence visible spectra of TbF_3

All the optical measurements were made along the crystallographic axis [100] of the TbF_3 crystal. The low temperature ($T = 92$ K) absorption and emission lines are concentrated within the wavelength range from 482 to 497 nm (i.e., from 20120 cm^{-1} to 20747 cm^{-1}). The absorption (dotted lines) and emission (solid lines) spectra are shown in **Fig. 2**.

The strong absorption due to the optical transitions from the lowest state of the ground $^7\text{F}_6$ multiplet of Tb^{3+} ion to the Stark levels of the excited $^5\text{D}_4$ multiplet is shown by the dotted lines designated as 1 – 5 in **Fig. 2**. The remaining weak absorption lines indicated by the numbers from 6 to 11 correspond to optical transitions originating from excited sublevels of the ground $^7\text{F}_6$ multiplet. The measured fluorescence spectra (solid lines and primed numbers) associated with $^5\text{D}_4$ luminescence to the $^7\text{F}_6$ ground state multiplet levels of Tb^{3+} at 90 K is also shown in **Fig. 2**. As can be seen from this figure, similar bands (though with differing intensity) are observed in the absorption and luminescence spectra at $\lambda \approx 483, 488, \text{ and } 489.5 \text{ nm}$. The wavelengths of the overlapping lines 1', 2', 3', 7', 8' and 9', 10', 11' observed in the luminescence spectra coincide with those of 1, 2, 3, 7, 8 and 9, 10, 11, respectively, found in the absorption spectra.

The coincidence of energies of absorption and luminescence lines in the optical spectra of TbF_3 and their temperature dependence facilitates construction of a scheme of the optical transitions in the absorption and luminescence spectra (see **Fig. 3**) and helps to establish the energies of most of the Stark sub-levels of the ground $^7\text{F}_6$ and excited $^5\text{D}_4$ multiplets split by the low-symmetry crystalline environment of the Tb^{3+} ion (C_S symmetry [1, 9]) in the TbF_3 orthorhombic crystal. The two panels of **Fig. 3** present the energy level scheme determined from the absorption spectra (left panel) and from the luminescence spectra (right panel). As can be seen in the two panels of **Fig. 3**, there is good coincidence in the Stark sub-level energies of the $^7\text{F}_6$ and $^5\text{D}_4$ multiplets found by analyzing the absorption and luminescence spectra for $T = 90$ K, notable exceptions being the sub-levels with energy 65 cm^{-1} and 20670 cm^{-1} , which are found in the luminescence spectra only. The “quasi-doublet” 65 cm^{-1} level was not found in [18], but a detailed comparison of the data from that paper with the current spectra measurements leads to a qualitative agreement with the rest of the quantum states. The magnetic property analysis, given in **section IV** below, shows that the lowest state of the $^7\text{F}_6$ ground multiplet is a “quasi-doublet.” It then follows that the singlet, and “quasi-

doublet” character of each of the other Stark sub-levels is as indicated in **Fig. 3**, in accordance with the results of [18].

3.2. Magneto-optical visible spectra of TbF₃

As mentioned in **section II**, the Faraday effect in TbF₃ (as well as in the biaxial TbAlO₃ [14,17]) is measured against the background of a large natural birefringence Δn [10,11]. Consequently, at a fixed temperature T and sample thickness l , the rotation angle θ of the major axis of the polarization ellipse oscillates as a function of wavelength λ , as shown in **Fig. 4**, where the tangent of 2θ is plotted as a function of wavelength (in nm) at two different temperatures $T = 92$ and 300 K. We see in **Fig. 4** that the amplitude of oscillation of the angle θ significantly increases as the temperature is lowered from 300 to 92 K, since the amplitude of the tangent of 2θ is proportional to the FE angle α_F [11].

Comparing the dependences of angle θ on wavelength λ measured along the crystallographic direction a both for the TbF₃ crystal with thickness 1.7 mm (**Fig. 4**) and for the TbAlO₃ crystal with thickness 0.145 mm (**Fig. 5**), one can observe an increase in the oscillation period of angle θ with a decrease in the crystal thickness. As a result, the FE of TbF₃ can be calculated from the spectral and temperature dependences of the rotation angles θ measured for remagnetized crystal along the [100] axis between 430-700 nm, and at temperatures 92 K and 300 K using the following data processing scheme from [14, 17].

For this scheme, it is necessary first to define a spectral dependence of Δn using the fact that the phase shift between neighboring extrema of the spectral dependence of θ angle is 180° for wavelengths λ_1 and λ_2 . Then we can obtain from formula (2):

$$\Delta n = \frac{\lambda_1 \lambda_2}{(\lambda_2 - \lambda_1)l} \quad (3)$$

respectively, where l is the crystal thickness. Further, with the use of the relation between the Verdet constant V and rotation angle θ in the external magnetic field H :

$$V = \frac{2\pi \cdot \Delta n}{\lambda} \left(\frac{\theta}{H} \right) \quad (4)$$

we can find values of the Verdet constant corresponding to “mean” values of the wavelengths λ from the spectral intervals $\Delta\lambda = (\lambda_2 - \lambda_1)$.

Analysis of the oscillation dependences of the angle θ (**Fig. 4** and **Fig. 5**) shows that in the TbF₃ crystal, the value of the natural birefringence ($\Delta n \approx 0.0186$) remains nearly constant within the wavelength range from 430 to 700 nm for temperatures 92 and 300 K. By contrast, in TbAlO₃

the value Δn monotonically decreases (from 0.0155 to 0.014) with increasing wavelength, which is in good agreement with similar data in [14].

It is important to note that because of the relatively weak change in Δn with respect to changing temperature (92 – 300 K) in the TbF_3 crystal, it is not possible to observe a sufficient number (at least 5 or 6 are needed) of the oscillation peaks of the angle $\theta(T)$ needed for reliable construction of the temperature dependence of the Verde constant V of this crystal. For example, in TbF_3 for the wavelength $\lambda = 510$ nm within the temperature range 92 – 300 K only three peak values of the angle θ were found for the crystal thickness 1.7 mm. By contrast, six peak values of the angle $\theta(T)$ at $\lambda = 506$ nm were found in a 1.5 mm thick terbium orthoaluminate crystal TbAlO_3 within the same temperature range [17], allowing accurate determination of the temperature dependence of the Verde constant V of this crystal.

The behavior of the spectral- and temperature-dependence of the natural birefringence Δn found in TbF_3 and TbAlO_3 crystals [14, 17] can be explained as follows. The lattice of TbF_3 is purely orthorhombic while the lattice of terbium orthoaluminate can be represented as a combination of two “quasicubic” sublattices inserted inside each other and forming a perovskite structure [19]. Evidently, in TbAlO_3 a differing temperature course of the lattice constants of these “quasicubic” sublattices leads to the complicated behavior of natural birefringence observed when there are changes in both crystal temperature and wavelength.

The results for the Verdet constant V calculated using formula (4) and the experimental data measured in TbF_3 along the axis [100] at 92 K and 300 K are presented in **Fig. 6**. As well as there being an increase in oscillation amplitude of the angle θ with respect to decreasing sample temperature, as shown in **Fig. 4**, there is also an increase in the Verdet constant V when the temperature drops, as shown in **Fig. 6**.

IV. Faraday rotation and magnetic susceptibility of TbF_3

4.1. Magnetic susceptibility of TbF_3

According to magnetic measurements [2], the Tb^{3+} ions occupy two crystallographically non-equivalent positions of monoclinic symmetry [9] in the TbF_3 crystal (similar to TbAlO_3 orthoaluminate [3,16]), as presented in the inset of **Fig. 7**. These positions differ from each other in orientation of both the crystalline environment and anisotropy axes (including the magnetic anisotropy [2]).

Since Tb^{3+} ($4f^8$) is a non-Kramers ion [3], each $^{2S+1}L_J$ multiplet splits into $(2J+1)$ non-degenerate Stark levels (singlets) when the RE ion enters low symmetry (C_s) sites in the orthorhombic lattice of TbF_3 . As a result, the magnetization of the non-Kramers RE ion sublattice in

the TbF₃ structure may arise only when the effect of mixing of Stark level wavefunctions having nearly the same energy (called “quasi-doublets” [3, 16]) in an external magnetic field H (the Van-Vleck mechanism [3]) is taken into account.

Following from previous results [2], the maximal magnetic susceptibility of the TbF₃ crystal is observed in the ac plane, where it is strongly anisotropic ($\chi_a > \chi_c$), whereas along the b axis χ_b is less than χ_a and has a Van-Vleck character [3,16]. The similar anisotropic behavior of the TbF₃ magnetic susceptibility is due to the fact that the ground state of the ⁷F₆ multiplet of the Tb³⁺ in the crystalline field C_s symmetry is a “quasi-doublet”. It is important to note that this “quasi-doublet” state is formed by two Stark sub-levels with nearly identical energy values, but with wave functions described by two different irreducible representations of the point group C_s : A and B [1,3,16].

The Tb³⁺ ion in TbF₃ thus can be treated as an “Ising” ion with its Ising axis taken as the magnetic anisotropy axis lying in the ac plane of the orthorhombic crystal, at an angle of $\alpha_0 = \pm 28^\circ$ with respect to the a axis (see inset of **Fig. 7**). The $\pm$ signs belong to two crystallographically-nonequivalent sites differing in the orientation of the local axes. We then choose the “Ising” axis as the z -axis of the local coordinate system of the Tb³⁺ ion (located at one of the nonequivalent sites) so that the y -axis is parallel to the b ([010]) axis of the orthorhombic crystal. In this local coordinate system, the wave functions of the ground “quasidoublet”, which have different irreducible representations (irreps.) of the C_s group (A and B), can be adequately approximated by the following linear combinations of “pure” $|J, \pm M_J\rangle$ states [2]:

$$|A\rangle, |B\rangle = \frac{1}{\sqrt{2}}(|J=6, M_J = +6\rangle \pm |J=6, M_J = -6\rangle) \quad (5)$$

where the top (symmetric) sign of $\pm$ refers to the state A and the bottom (antisymmetric) sign refers to state B .

This ground state of the Tb³⁺ ion in TbF₃ leads to the fact that its magnetic moment is in the ac plane for any orientation of the external magnetic field and close to a maximally possible value $m_0 \approx 9\mu_B$ along the “Ising” axis [3,16]. On the other hand, the Van-Vleck origin of the magnetic susceptibility χ_b along the b axis can be associated with a “quasi-doublet” state at an energy of 65 cm⁻¹ in the spectrum of the ground ⁷F₆ multiplet. The wave functions of this first excited “quasi-doublet” at 65 cm⁻¹ have different symmetries A and B , and the molar magnetic susceptibility along the y -axis of the local coordinate system can be represented as [3]:

$$\chi_y^m \equiv \chi_{VV}^m = g_0^2 \mu_B^2 N_A \left[\frac{|\langle A | \hat{J}_y | A' \rangle|^2}{E_A^{(1)}} + \frac{|\langle B | \hat{J}_y | B' \rangle|^2}{E_B^{(1)}} \right] \quad (6)$$

where $g_0 = 1.5$ is the Lande factor of the ground 7F_6 multiplet of the Tb^{3+} ion and N_A is Avogadro's number. The molar susceptibility is related to the dimensionless magnetic susceptibility χ , as

$$\chi^m = \chi \frac{M}{\rho}, \text{ where } \rho = 7.23 \text{ (g/cm}^3\text{)} \text{ is the density and } M = 216 \text{ g/mole is the molar mass of TbF}_3.$$

The value of the Van-Vleck susceptibility χ_b can be explained by assuming that the wave functions of the first excited “quasi-doublet” at 65 cm^{-1} , $|A'\rangle$, $|B'\rangle$ can be written as:

$$|A'\rangle, |B'\rangle = \frac{1}{\sqrt{2}}(|J=6, M_J = +5\rangle \mp |J=6, M_J = -5\rangle) \quad (7)$$

In this case, assuming that $E_A^{(1)} \approx E_B^{(1)} = k_B T_1 = 65 \text{ cm}^{-1}$, where $T_1 = 94.5 \text{ K}$ and $\frac{N_A \mu_B^2}{3k_B} = \frac{1}{8} (\text{cm}^3 \cdot \text{K/mole})$, we obtain $\chi_b^{(m)} \equiv \chi_{VV}^{(m)} = \frac{6(g_0 \sqrt{3})^2}{8T_1} = 0.05414 \text{ (cm}^3\text{/mole)}$, which is in good agreement with the experimental data [2] extrapolated to $T = 0 \text{ K}$.

When the temperature is raised, the behavior of TbF_3 magnetic properties becomes significantly more complicated. Then in addition to the above-mentioned anisotropy in χ , the inverse magnetic susceptibility χ_b is nonlinearly dependent on T , as shown in **Fig. 7**. A part of the nontrivial temperature dependence of χ_b can be explained by a significant mixing of the wave functions $|A'\rangle$, $|B'\rangle$ of the first excited “quasi-doublet” at 65 cm^{-1} with the wave function $|B''\rangle$ of the Stark singlet lying near 114 cm^{-1} . The wavefunction for this Stark singlet can be approximated as:

$$|B''\rangle = \frac{1}{\sqrt{2}}(|J=6, M_J = +4\rangle - |J=6, M_J = -4\rangle) \quad (8)$$

Another contribution to the temperature dependence of χ_b is made by the state located at 190 cm^{-1} , which becomes thermally populated at room temperature. This “quasi-doublet” state is formed from two excited Stark singlets whose wave functions transform according to the same irrep of the symmetry group $C_S(A'', A''')$. Note that the magnetic moment μ_1 associated with this state is directed along the y -axis of the local coordinate system of the RE ion (i.e., the $[010]$ crystal axis) and shows “Ising-like” behavior. According to our estimation, its magnitude is nearly maximal, and has a value of $\mu_1 \approx 8.2 \mu_B$.

Therefore, if an external field is directed along the $[010]$ axis of the orthorhombic crystal, we should take into account not only the mixing between the wavefunctions of the ground “quasi-doublet” states (A , B) and the first excited “quasi-doublet” states (A' , B'), but also the mixing between the wavefunctions of the first excited “quasi-doublet” states (A' , B') with the Stark singlet B'' located near 114 cm^{-1} . Furthermore, the 190 cm^{-1} “quasidoublet” states (A'' , A''') become

populated at higher temperatures, and consequently their contribution to the magnetic moment of the Tb^{3+} ion becomes significant.

In accordance with the above-mentioned details, an expression for the transverse molar magnetic susceptibility χ_b that is valid at high temperatures has the form:

$$\chi_b^{(m)} = \frac{N_A \mu_B^2}{k_B} \left[\frac{13.5}{T_1} (\rho_0 - \rho_1) + \frac{12.4}{(T_2 - T_1)} (\rho_1 - \rho_2) + \frac{22.5}{T} \rho_3 \right] \quad (9)$$

where $T_2 = 164.5$ K; ρ_0 , ρ_1 , ρ_2 and ρ_3 are the Boltzmann populations of the ground and first excited “quasi-doublet” states at 0 cm^{-1} and 65 cm^{-1} , the singlet 114 cm^{-1} state, and the “quasi-doublet” 190 cm^{-1} state, respectively. The statistical sum Z_0 in the expressions for the Boltzmann populations $\rho_{0,1,2,3}$ is determined as:

$$Z_0 = 2 + 2 \exp(-65/kT) + \exp(-114/kT) + \exp(-181/kT) + 2 \exp(-190/kT) + \exp(-257/kT) + \exp(-273/kT) + \exp(-443/kT) \quad (10)$$

The calculated results of the χ_b temperature dependence obtained from expression (9) are plotted in **Fig. 7**, from which it is seen that the experimental [2] and theoretical values of the transverse magnetic susceptibility χ_b in the investigated temperature range $4.2 - 300$ K are in a good qualitative agreement.

4.2. Faraday effect of TbF_3

According to *Stephens* [20], the temperature-dependent contribution to the Faraday effect of the non-Kramers RE ion, α_F^C (the paramagnetic *C*-term [15,16]) can arise only if the effect of Van-Vleck mixing in an external magnetic field H of two close-lying Stark singlets a and b (forming a ground-state “quasidoublet”) is taken into account. Then, the expression for the *C*-term of the FE at frequencies ω far from the resonance “effective” frequency ω_0 of the spin- and parity-allowed electric-dipole (ED) transitions $4f \rightarrow 5d$ (or $5g$), can be represented as [20]:

$$\alpha_F^C = \frac{\pi N}{c n h} \frac{(n^2 + 2)^2}{9} \frac{\omega^2}{(\omega_0^2 - \omega^2)} H \frac{1}{d_0} \sum_{a,b,j} \frac{\text{Im}[\langle a | \hat{\mu}_z | b \rangle \langle b | \hat{P}_x | j \rangle \langle j | \hat{P}_y | a \rangle - \langle b | \hat{P}_y | j \rangle \langle j | \hat{P}_x | a \rangle]}{kT} \quad (11)$$

where $\hat{P}_x, \hat{P}_y$ are the operators of the corresponding ED components of the RE ion, $\hat{\mu}_z = -g_0 \mu_B \hat{J}_z$ is the operator of the z -projection of the magnetic moment, N is the number of RE ions per cm^3 , and $d_0 = 2$ is the degree of degeneracy of the ground state. The wave functions $|a\rangle$ and $|b\rangle$ correspond to the lowest-energy “quasidoublet” Stark sublevels, and $|j\rangle$ is the wave function of the Stark singlet of the excited $4f^{(n-1)}5d$ configuration at which the optical transition with frequency ω_0 takes place.

Thus, we can see that the “paramagnetic” contribution to the FE measured along the z -axis of the local coordinate system is proportional to the product of the matrix elements of the electric-dipole (ED) transitions between the a , b states of the ground-state “quasidoublet” and the excited state j , and the magnetic dipole (MD) transitions between the Stark levels within the “quasidoublet.” Based on group theory arguments, one can show that the existence of the Faraday effect in TbF_3 along the $[100]$ axis (i.e., in the ac plane) is connected with the opposite symmetry (A and B) of the two sublevels of the ground “quasi-doublet” in the 7F_6 multiplet. This observation directly confirms the results obtained from the analysis of the magnetic susceptibility of TbF_3 performed below, where it is shown that the wavefunctions of the ground “quasidoublet” can be approximated by a linear combination of pure $|J, \pm M_J\rangle$ states $|6, \pm 6\rangle$ in the local “Ising” coordinate system of the Tb^{3+} ion in TbF_3 .

The Wigner-Eckhart theorem [19] can be used to evaluate the matrix elements in equation (11) for the spin- and parity-allowed ED $4f \rightarrow 5d$ transitions arising between the ground ($L_0 S_0 J_0$) multiplet of the $4f^{(n)}$ -configuration and the ($L = L_0 - 1, S_0$) term of the excited $4f^{(n-1)}5d$ configuration of the Tb^{3+} ion. If the splitting of the sublevels (following the Judd-Ofelt approximation [21]) in the summation of formula (11) over the excited states belonging to the mixed excited $4f^{(n-1)}5d$ configuration of RE ion is also neglected, then it is possible to obtain the following expression for the “paramagnetic” contribution to the Verdet constant of TbF_3 :

$$V^C = K \frac{\omega^2}{(\omega_0^2 - \omega^2)} \chi \quad (12)$$

where,

$$K = \frac{2\pi e^2}{c\hbar\mu_B} \cdot \frac{(n+2)^2}{9} \langle r \rangle^2 \frac{(2-g_0)}{g_0} \left[24/G^2 \frac{(2L+1)}{L_0(2S_0+1)} \left\{ \begin{matrix} L_1 & L_0 & 3 \\ 1 & 2 & L \end{matrix} \right\}^2 \right] \quad (13)$$

The constant K in equation (12) can be approximated by examining its form in formula (13). For example, $\langle r \rangle = \langle 4f|r|5d \rangle$ is the radial integral for the $4f$ and $5d$ states, values of which can be modeled [21]; $G_{S_0 L_0}^{S_0 L_0} = \frac{1}{\sqrt{7}}$ is the genealogical coefficient (or coefficients of fractional parentage) [19]; $\left\{ \begin{matrix} L_1 & L_0 & 3 \\ 1 & 2 & L \end{matrix} \right\}$ is a $6j$ -symbol [19], where $L_0 = 3$ and $L_1 = 0$ are the orbital moments of the Tb^{3+} ion the ground term and $4f^{(n-1)}$ “core”, respectively; $L = 2$ is the orbital moment of the excited LS_0 term which results from the electrostatic interaction between the $5d$ electron and the $4f^{(n-1)}$ “core” states of the RE ion. Note that in the approximation of the “average” crystal field [22] in Tb^{3+} , the only allowed optical $4f \rightarrow 5d$ transitions are of the type: $L_0 S_0 \rightarrow (L_0 - 1) S_0$ (i.e., transitions from the ground term 7F to the excited term 7D). The numerical value for the coefficient K in expressions

(12) and (13) is $0.803 \text{ rad}\cdot\text{cm}^{-1}\cdot\text{Oe}^{-1}$, based on optical and atomic parameters reported in the literature for Tb^{3+} in TbF_3 [12,18].

These results (as well as those of the orthoaluminate TbAlO_3 [14,16,17]) show that the spectral dependences $V(\chi)$ for TbF_3 are linear (following expression (12)) in the temperature range from 90 to 300 K. A detailed analysis of these dependences by the method described in [14] allows determination of the values for the coefficient $K = 0.76 \text{ rad}\cdot\text{cm}^{-1}\cdot\text{Oe}^{-1}$ and the “effective” frequency $\omega_0 = 88.87 \cdot 10^{14} \text{ s}^{-1}$ (corresponding to $\lambda_0 = 212 \text{ nm}$) of the allowed transitions responsible for the FE in TbF_3 . The difference in numerical and experimentally defined values of coefficient K reflects both the uncertainty in the experimental data and the assumptions made in calculating the given magneto-optical constant. Processing of the experimental data showed also that the temperature-independent contribution B to FE for TbF_3 is smaller than the experimental error. The above conducted analysis as well as the fact that the “effective” frequency in TbF_3 is close to the similar frequency of the first allowed $4f \rightarrow 5d$ transitions of RE orthoaluminate TbAlO_3 make us conclude that the FE of TbF_3 in the investigated spectral range is generally due to electric-dipole transitions.

V. Conclusions

This study of the optical and magneto-optical spectra of the Tb^{3+} ion in TbF_3 allows us to make the following conclusions. The optical-quality TbF_3 crystals grown from melt by the Bridgman technique are single-phase, of structural type $\beta\text{-YF}_3$ (space group $Pnma$) with lattice parameters $a = 6.5109 \text{ \AA}$, $b = 6.9482 \text{ \AA}$, $c = 4.3886 \text{ \AA}$. Optical measurements made at low temperature (90 K) along the crystallographic axis [100] indicate the energy level structure of the ground 7F_6 multiplet includes “quasi-doublet” states at energies of 0 cm^{-1} (A, B), 65 cm^{-1} (A', B') and 190 cm^{-1} (A'', A'''), and also a singlet sublevel 114 cm^{-1} (B'') that are important for understanding the FE of Tb^{3+} in TbF_3 . The Van-Vleck’s behavior of the magnetic susceptibility χ_b can be satisfactorily explained by the magnetic mixing of the wavefunctions belonging to the ground and first excited “quasidoublet” states (lying at 65 cm^{-1}) of the ground 7F_6 multiplet of Tb^{3+} ion in the TbF_3 structure. Analysis of the oscillation dependences of the rotation angle θ shows that in the TbF_3 crystal a value of the natural birefringence ($\Delta n \approx 0.0186$) remains nearly constant within the wavelength of 430-700 nm for temperatures 92 K and 300 K in comparison with TbAlO_3 where the value Δn monotonically changes not only with increasing wavelength, but also with decreasing temperature. As the temperature decreases from 300 K down to 92 K, we find significant increases in the oscillation amplitude of the rotation angle and in the Verdet constant V . Our experimental results show that the spectral dependences $V(\chi)$ for TbF_3 are linear in the temperature interval 92 – 300 K. Moreover, the experimental results allow us to conclude that the MOA of TbF_3 in the investigated spectral

range is generally caused by the spin- and parity-allowed electric-dipole $4f \rightarrow 5d$ transitions in the Ce^{3+} ions.
